## **Abstract**

The ‘quiet eye’ (QE) – a period of extended gaze fixation on a target – has been reported in many tasks that require accurate aiming. Longer quiet eye durations (QED) are reported in experts compared to non-experts and on successful versus less successful trials. The QE has largely been studied in the field and the cognitive mechanisms underlying QE are not fully understood. We investigated the QEDs of 10 expert and 10 novice archers in the field, and in the laboratory using a computer-based archery task. The computer task consisted of shooting archery targets using a joystick. Random ‘noise’ (visual motion perturbation) was introduced at high and low levels to allow for the controlled examination of the effects of task complexity and processing demands. In this task, we also tested an additional group of 10 non-archers. In both field and laboratory tasks, eye movements were measured using electro-oculography. The expert archers exhibited longer QED compared to the novice archers in the field task. In the computer task, the archers again exhibited longer QEDs and were more accurate compared to non-archers. Furthermore, expert archers showed earlier QE onsets and longer QEDs during High Noise conditions compared to the novices and non-archers, as well as in the High Noise compared to the Low Noise condition. Our findings show skill-based effects on QED in field conditions and in a novel computer-based archery task, in which online (visual) perturbations modulated experts’ QEDs. These longer QEDs in experts may be used for more efficient programming in which accurate predictions are facilitated by attention control.

**Keywords:** gaze; experts, aiming; programming; attention

## 1. Introduction

Scientists examining the gaze behaviours employed by expert performers across several domains have improved our understanding of the perceptual-cognitive mechanisms that are characteristic of skilled performance (for reviews, see Mann, Williams, Ward, & Janelle, 2007; Rienhoff, Tirp, Strauß, Baker, & Schorer, 2016). In the field of sports science, for example, researchers have shown that, in certain sports, expert performers often employ fewer fixations of longer durations compared with non-experts, resulting in a more efficient extraction of task-relevant information (Mann et al., 2007; Williams & Davids, 1998; Williams, Davids, Burwitz, & Williams, 1994). Similarly, Vickers (1992) highlighted distinct gaze patterns between expert and novice golfers while performing putts and identified that experts kept a steady gaze or “quiet eye” (QE) at a specific location before ball contact. The QE was subsequently formally defined as the duration of the final fixation or tracking gaze on a target within a threshold of 3° (or less) and has a minimum duration of 100 ms. The onset of the QE occurs prior to the final action of the task and the offset is identified when eye movements fall outside the threshold (Vickers, 1996).

Furthermore, with the use of video-based mobile eye trackers, longer quiet eye durations (QEDs) have been reported to be characteristic of experts compared with non-experts, and on successful compared with less successful performance, in many aiming sports, including shooting (Causer, Bennett, Holmes, Janelle, & Williams, 2010), darts (Rienhoff et al., 2013), and billiards (Williams, Singer, & Frehlich, 2002). In addition, the QE has been successfully used as a training tool (where to look and for how long) with improvements in performance linked to relative increases in QED (see Vine, Moore, & Wilson, 2014) in different targeting sports (Causer, Holmes, & Williams, 2011; Moore,

1 Vine, Cooke, Ring, & Wilson, 2012; Vine & Wilson, 2011) and recently, both in the  
2 training of surgical skills (Causer, Harvey, Snelgrove, Arsenault, & Vickers, 2014) and  
3 motor skills in clinical populations (Miles, Wood, Vine, Vickers, & Wilson, 2015).

4 A number of mechanisms have been proposed to explain the QE and its effect on  
5 performance. Published reports support a programming hypothesis (Horn, Okumura,  
6 Alexander, Gardin, & Sylvester, 2012; Mann, Coombes, Mousseau, & Janelle, 2011;  
7 Williams et al., 2002). The QE period is suggested to facilitate information processing and  
8 its duration is thought to reflect the time needed to program and fine-tune a movement  
9 response. Thus, longer QEDs are thought to extend this critical motor preparation period,  
10 enhancing performance (Mann et al., 2011; Vickers, 2011). Williams et al. (2002) reported  
11 longer QEDs with increased levels of task complexity, when manipulating the distance of a  
12 billiards shot (near versus far) and the time allowed to complete a specific shot (constrained  
13 versus unconstrained time). Their findings support the programming hypothesis in that  
14 longer QEDs correspond to the greater information processing demands for complex tasks,  
15 requiring longer programming times. However, this very general explanation does not fully  
16 describe the positive facilitatory effects of the QE or define the actual information that is  
17 being processed (Gonzalez et al., 2015). Furthermore, the notion that experts have longer  
18 QEDs reflecting prolonged attention and motor preparation time questions whether only  
19 open-loop programming mechanisms are active during this extended time (Vine, Lee,  
20 Moore, & Wilson, 2013).

21 Current models of motor control suggest that skilled behaviour relies on a  
22 combination of sensory feedback and predictions of both our own body and the tools we  
23 interact with to accurately estimate the consequences of a motor response (Wolpert &

1 Flanagan, 2001). The combination of the two streams of information (motor prediction and  
2 sensory feedback) enhances perceptual-motor performance (Shadmehr, Smith, & Krakauer,  
3 2010), since making inaccurate predictions or solely relying on feedback can be costly in  
4 terms of accuracy and timing. In line with this model, researchers examining QE  
5 mechanisms and their effects on performance have suggested that the QEDs facilitates  
6 programming and that the inclusion of online control mechanisms under visual guidance  
7 aids the maintenance of the QE (Causser, Hayes, Hooper, & Bennett, 2016; Vine, Lee,  
8 Walters-Symons, & Wilson, 2017; Vine et al., 2013). This latter conclusion is in accordance  
9 with QED findings which suggest that late information pick-up is important for accuracy  
10 and continued gaze control is critical for preventing performance failure in expert golfers  
11 (Vine et al., 2013). Causser et al. (2016) examined the effects of online control using visual  
12 occlusion during movement initiation in a golf putting task and found that performance on a  
13 putting task suffered without the availability of visual online control during the QE. They  
14 concluded that the QE reflects programming and the inclusion of online control, but that  
15 online control is critical to performance. Furthermore, having continuous online information  
16 (of the target, environment and/or limb) available to make predictions has been shown to  
17 benefit performance overall, since the accuracy of the internal representations (e.g., of the  
18 target) may decay over time (Heath & Binsted, 2007).

19 Klostermann, Kredel and Hossner (2013) investigated the performance-enhancing  
20 effects of experimentally manipulated QEDs in an externally paced throwing task by  
21 presenting a target at different timings (short and long presentations, similar to Williams et  
22 al., 2002) and locations (random and predictive) during movement unfolding. The  
23 facilitatory effects of longer QEDs were apparent only under a high information-processing

1 load (short and random target presentations) and that QED effects on performance seemed  
2 to disappear with increased predictability of the target's location and decreased task  
3 demands. Klostermann et al. (2013) argued that the predictability of the target might have  
4 facilitated relevant information processing (as early programming) that was not required  
5 during the QE period; consequently, long QEDs were "dispensable" under conditions of  
6 high predictability and low task demands, compared to when the target was perturbed into  
7 random locations. Moreover, in the less demanding task, the lack of absolute QEDs and  
8 performance differences between the short and long target presentations reflected the  
9 availability of crucial online movement control for the responses. However, they suggested  
10 a need for further QE studies that focus on disturbing these online mechanisms. In line with  
11 Williams et al. (2002) and Horn et al. (2012), Klostermann et al. described their findings as  
12 part of the information processing explanation but noted that the exact nature of these  
13 processing demands were not known and results could be explained by attention control  
14 mechanisms (i.e., in random target presentations attentional costs for late stimulus  
15 identification were high). Thus, programming alone may not result in performance  
16 enhancing QEDs.

17 In regards to attention control, Vickers (2009) suggested that the QE involves top-  
18 down (dorsal stream) control mechanisms to guide attention and program a response, while  
19 suppressing intrusive bottom-up (ventral stream) responses. In line with this inhibition  
20 hypothesis, Klostermann, Kredel, and Hossner (2014) examined the links between attention  
21 and QED and suggested the involvement of additional functions during this steady gaze  
22 period, mainly, (inhibitory) attention control mechanisms to explain the facilitatory effects  
23 associated with a longer QED. The inclusion of inhibitory mechanisms is in accordance

1 with the control and maintenance of attention and reflects higher order cognitive control  
2 (Deubel & Schneider, 1996; Findlay, 2009; Rizzolatti, Riggio, Dascola, & Umilti, 1987),  
3 which may be implemented during the QE (Gonzalez et al., 2015). In addition, it is  
4 attention control strategies that have mainly been implemented in QE training studies,  
5 resulting in improvements in performance (see Vine et al., 2014). It may be that inhibitory  
6 control allows for experts to select the most relevant information, maximizing the speed and  
7 accuracy of online processing to better predict a motor response (motor program). Thus,  
8 experts may rely on predictions to filter sensory information (Wolpert & Flanagan, 2001)  
9 and to produce timely responses rather than solely relying on sensory input, which is slower  
10 and more susceptible to noise.

11         Given that QED effects have been associated with complex tasks that require online  
12 control and late information pick-up, it may be that continuous monitoring of (afferent)  
13 signals, including visual and proprioceptive information, are integrated during the QED and  
14 afforded by gaze and attention control mechanisms. Thus, the QE may involve a more  
15 complex neural network than suggested by the programming hypothesis. The difficulty in  
16 studying such behaviour lies in the fact that field manipulations to examine the proposed  
17 underlying mechanisms are limited. Furthermore, establishing a relationship between QED  
18 and performance may be difficult in the field due to the fact that differences in performance  
19 accuracy may not necessarily be directly related to a specific QED or to the high variability  
20 that may be encountered in this environment, such as the existence of background  
21 distractions and/or distinct differences in movement characteristics when shooting or  
22 throwing between groups. However, since QED effects have been observed under more  
23 controlled conditions (e.g., Klostermann et al., 2013), it seems promising that the

1 mechanisms underlying the QE can be explored in a carefully controlled laboratory  
2 environment, away from the sports field. For example, Behan and Wilson (2008)  
3 implemented a computer archery task completed by non-experts under two anxiety  
4 conditions. Their results replicated previous *in situ* findings related to the effects of anxiety  
5 on the QED and pointed to links between attention control and QE, although these effects  
6 (as well as Klosterman et al's 2013 findings) were not related to expertise *per se*. Given that  
7 the QE has been described within the expertise model, controlled investigations into this  
8 gaze strategy in experts compared to non-experts may provide more accurate knowledge of  
9 the QE.

10 In this paper, we had two aims. First, we examined skill-related differences in QED  
11 between expert, Olympic-level archers and novice archers in the field. To our knowledge,  
12 this is the first attempt to examine distinct aiming gaze behaviour between experts and  
13 novices in the sport of archery. To achieve this aim, we measured gaze (QED) and  
14 performance (radial error and scores). We expected skill-related QED differences in  
15 accordance with previous research in aiming sports, with experts having a longer QED and  
16 better accuracy (e.g., Causer et al., 2010; Rienhoff et al., 2013).

17 Our second aim was to design a computer-based, archery task that would allow for a  
18 controlled examination of QED and performance across our expert and novice archers and  
19 would replicate the QED field results. Moreover, we aimed to minimise field 'noise'  
20 variability (e.g., differences in technique, location, equipment), isolate expert archers' gaze  
21 aiming strategies (from motor expertise) and examine how these would impact  
22 performance. In line with the current theories of online integration and attention control, we  
23 manipulated task difficulty in the computer-based task using two conditions involving two

different levels of visual perturbation while participants attempted to aim at an archery target. More specifically, we implemented a ‘High Noise’ (HN) condition in which the requirement of online motor control was higher than in a less difficult and more predictable ‘Low Noise’ (LN) condition by perturbing the aiming crosshair. Unlike Behan and Wilson’s (2008) simulated experiment which included an anxiety manipulation and non-archers, we included archery experts, novices, and an additional control group (non-expert, non-archer) to better identify expert-related QED differences in our computer task. We hypothesised similar results to those expected in the field in that the expert archers would show a longer QED than novice archers and non-archers indicating that some of the gaze strategies used by experts can be identified and examined in a computer task. Also, we predicted longer QEDs in the more complex HN condition when compared with the LN condition. We further hypothesised that differences in QEDs across groups would reflect the ability to override the added crosshair’s noise (visual perturbation) and continuous updating, which could lead to temporal lags and errors in performance, particularly in the HN condition.

## **2. Methods**

### **2.1 Participants**

We recruited 30 participants. The expert group comprised of 10 Olympic level archers from the Team GB Archery team who had at least two years of competitive experience at international level (mean age and SD:  $26 \pm 10.02$  years; 7 males and 3 females; mean archery experience:  $11.42 \pm 5.97$  years; mean training time:  $34.45 \pm 7.52$  hours/week). The 10 novice archers were members of the university archery club who had experience of at least one national inter-university competition (age:  $31.09 \pm 13.56$  years; 6

1 males and 4 females; mean archery experience:  $1.98 \pm 0.94$  years and a mean training time:  
2  $4.36 \pm 2.83$  hours/week). The 10 non-archers were university students (age:  $25.5 \pm 2.51$   
3 years; 6 males and 4 females), recruited from the undergraduate population. All participants  
4 were right handed, had normal eyesight and no known neurological or developmental  
5 conditions. None of the archers reported any experience in computer archery or any other  
6 aiming computer “games” and only two non-archers reported using videogames regularly (<  
7 4 hrs/week). This study was approved by the lead university’s local ethics committee and  
8 conducted in accordance with the ethical standards laid out in the 1964 Declaration of  
9 Helsinki. All participants provided informed consent.

## 10 **2.2 Procedure**

11 There were two experimental sessions involving a field and a computer task,  
12 respectively. For the field task, expert and novice archers were asked to shoot 24 arrows at  
13 an 80 cm archery target (10 multi-colour rings) located at 30 m distance (corresponding to  
14  $1.5^\circ$  of visual angle for the target’s diameter). The individual session commenced with a  
15 warm up (12 arrows at 10 m distance), followed by 12 practice shots at the 30 m target. For  
16 the experimental trials, archers were asked to shoot 6 arrows in a row, at will, in 4 blocks  
17 (24 arrows in total). Participants were able to see in which target ring their arrows landed  
18 (feedback) and were aware that their accuracy was recoded. The typical archery target has  
19 10 rings and each ring corresponds to a score ranging from 10 to 0, with 10 being the  
20 highest score corresponding to an arrow shot on target centre or “bull’s eye”, a score of 1  
21 for the last outer ring and a score of 0 for a complete miss. Rest breaks were provided in  
22 between each block, at which time the arrows were collected. The session lasted for  
23 approximately 90 min.

1       The computer task was designed using a custom made program (psychtoolbox 3,  
2       Matlab 2013a, The Mathworks, Inc). For this task, archers and non-archers were asked to  
3       shoot at an archery target (10 multi-color rings, 80 pixels in diameter) presented on a  
4       computer laptop (900 x 1600, 60 Hz, 15" Samsung Electronics Co), using a joystick (2 axis,  
5       Sidewinder, Microsoft Co). Participants were seated on an adjustable chair 60 cm from the  
6       computer screen (for an equivalent  $1.5^\circ$  of visual angle for the target's diameter, thus each  
7       ring was 8 pixels or  $0.15^\circ$  of visual angle) and rested their head on a chinrest to avoid head  
8       movements. Participants held the joystick, which was located in front of them, with their  
9       right hand and could be moved along the Y axis (upwards direction by pulling the joystick  
10      and downwards by pushing) and the X axis (right and left).

11      The experiment commenced with a visual 'Go!' signal, which indicated that the  
12      participant had to press the joystick's front button with his or her index finger to start a new  
13      trial, at which time, the target and crosshair (100 pixels in diameter) appeared,  
14      corresponding to the start of aiming time (Fig. 1). Participants then raised the crosshair to  
15      aim at the target by pulling the joystick backwards, while maintaining the joystick's front  
16      button pressed, to simulate drawback and elevation. Once they positioned the crosshair on  
17      the target they were asked to continue aiming at the target until a green 'light' flashed  
18      briefly above the target, 6 s after movement onset and for 250 ms. The green light indicated  
19      that participants were allowed to shoot at the target by releasing the button after the light  
20      disappeared (6.25 s after button press). Participants were instructed not to look at the green  
21      light directly and continue aiming, but to be aware of it by using peripheral vision. The  
22      green light set a minimum aiming time, which was implemented to avoid a quick 'pass-by'  
23      shooting (i.e., moving the crosshair across the target and guessing when to best release it)

and forced the participants to actively aim at the centre of the target, as they would in the field. Participants became habituated to this constraint after only a few trials. They were also made aware that they had a 30 s time limit to shoot in total, from when they started aiming. However, none of the participants reached this limit. After the button was released, a simulated arrow followed a parabolic trajectory to the target that reflected any positional error at the moment of release, and participants were able to see where the ‘arrow’ had landed on the target (feedback) within 2 s.

Participants performed the computer task under two conditions with distinct task complexities, namely, high noise (HN) and low noise (LN). This manipulation consisted of inducing random movement or ‘noise’ into the crosshair’s path as the participants attempted to aim at the target by moving the joystick. A set of 30 random X and Y paths were generated with a random number generator and then two different low pass filters were applied to create either a smoother, more predictable or a jerkier, less predictable 2D motion applied to the crosshair’s path. To make sure that the participants were familiar with the joystick and task, a total of 20 practice trials (10 high noise, 10 low noise) were given prior to experimental trials. There were a total of 60 experimental trials in which the HN and LN conditions were alternated every 15<sup>th</sup> shot (counterbalanced). Participants were told to aim and shoot at the target’s centre or “bull’s eye” after the green light disappeared but within the 30 s limit. For motivation, we alerted participants to the fact that their accuracy would be recorded. The computer task session lasted for approximately 60 min.

**-Fig 1-**

## 2.3 Measures

### 2.3.1 Gaze

Eye movements were measured using an electro-oculogram (EOG) bio-amplifier (gain of 100) with a band pass range from DC to 500 Hz (ADInstruments Ltd, Oxford, UK). The analog data were sampled at 1000 Hz and recorded on line using PowerLab data acquisition system and LabChart 5 software (ADInstruments Ltd, Oxford, UK). We implemented EOG techniques since the small electrodes placed on the archers' face did not interfere with their aiming and due to the fact that some archers tended to close an eye or squint when aiming, leading to data loss when pilot testing using a video-based, mobile eye tracker. In addition, head movements in archery are minimal. Thus, EOG measures were better suited for our experiments, providing information on eye movement amplitude measured relative to target centre as well as temporal information important for QE (i.e., fixation duration, QE onset and offset).

To measure horizontal and vertical eye movements (EOG<sub>h</sub> and EOG<sub>v</sub>), two Ag/AgCl electrodes were placed over the participant's right and left temples and two electrodes were placed above (on forehead) and below the right eye. A ground electrode was placed over the back of the left ear. Pre-processing of EOG signals were performed off-line using LabChart 5 (ADInstruments Ltd) and further analyses to identify QE were performed using custom made programs (for field and computer tasks) in Matlab (The Mathworks, Inc). EOG signals were bandpass filtered with low and high cut-off frequencies of 0.2-30 Hz respectively, to de-noise and remove drift from the signal (Marmor et al., 2011). Blinks were eliminated from each trial and the gaps were linked using linear interpolation.

1           Calibrations were performed in the field after each experimental block using the  
2 same target stand at 30 m. Participants fixated at a marked centre target (3 cm in diameter  
3 and visible to participants) for 2 s and then moved their eyes to fixate at marked right, left,  
4 upper and lower targets for 2 s, while returning to the centre target between each location  
5 ( $1^\circ$  movements for each location). This process was repeated twice for consistency for each  
6 block. For the computer task, following a centre fixation (2 s), 16 horizontal (8 right, 8 left)  
7 and 16 vertical (8 upwards and 8 downwards) cross targets (0.5 x 0.5 cm or 50 x 50 pixels)  
8 were presented sequentially for 2 s each, with separation of  $0.5^\circ$ , with the participant  
9 returning to the centre fixation point between each target.

10           The horizontal and vertical voltages at each positional jump in these calibrations  
11 (with respect to center and averaged over 1 s at each location) were recorded for each  
12 participant. Linear regressions were performed on the EOG data (see Berret, Bisio, Jacono,  
13 & Pozzo, 2014) and the resulting slopes (averaged for EOGv and for EOGh) were used to  
14 calculate the voltages that were equivalent to  $1^\circ$  for each participant. These EOGv and  
15 EOGh voltages were used as eye movement thresholds to identify the QE timings.

### 16           2.3.2 Quiet eye

17           We defined the QED as the period in which eye movements were maintained within  
18  $1^\circ$  of visual angle (0.5 and  $-0.5^\circ$  of visual angle relative to target centre) and for at least 100  
19 ms prior to arrow release. Our QE definition not include larger saccades that were outside of  
20 the target area also keeping within the definition of the QE as a fixation (see Gonzalez et al.,  
21 2015).

22           **Field task:** In the field tests, electromyography (EMG) techniques were used to  
23 measure muscle activation and identify the time at which the arrow was released. Ag/Ag Cl

1 electrodes were placed over the forearm, on the flexor digitorum superficialis (FDS)  
2 muscle with a ground electrode over the elbow. This signal was bandpass filtered with cut-  
3 off frequencies of 10-500 Hz, collected into the PowerLab system (also sampling at 1000  
4 Hz, using a bio-amplifier, gain 100) and recorded with LabChart 5 software  
5 (ADInstruments Ltd, Oxford, UK).

6 To identify the trial epochs, the EMG signal was rectified and low pass filtered with  
7 a cut-off frequency of 10 Hz to obtain the linear envelope. The start of the trial was  
8 identified as the time at which 50% of maximum FDS activation was achieved as a result of  
9 the draw back movement to start aiming. The sudden decrease in FDS muscle activation as  
10 a result of releasing the arrow was identified using the peak of the derivative of the EMG  
11 linear envelope. The start of aiming was always set to 0 s and the absolute difference  
12 between this start time and arrow release time was defined as the total response time (TRT).  
13 Eye movements were inspected during TRT derived from the EMG signal in Matlab. The  
14 QE onset and offset were identified by working backwards from arrow release time until  
15 either the vertical or horizontal EOG signal fell outside the 1° boundaries (0.5 and -0.5°  
16 relative to target centre).

17 **Computer task:** For the computer task, the joystick's button press was defined as  
18 the start time (set to 0 s) and button release corresponded to the arrow release. These event  
19 signals were fed into the data acquisition box and used as digital markers together with the  
20 EOG signals. As with the field task, the TRT was defined as the difference between arrow  
21 release and start time. Eye movements were inspected during this TRT and the QE  
22 onset/offset timings were identified by working backwards from arrow release time. In  
23 addition, the resulting EOG<sub>v</sub> and EOG<sub>h</sub> voltages obtained from the calibration were used to

1 identify the corresponding value for  $1^\circ$  ( $0.5^\circ$  and  $-0.5^\circ$  from target centre) for QED onset and  
2 offset detection (Fig. 2). Trials in which there was no QE or QED was less than 100 ms  
3 were excluded from all analyses. We additionally calculated QED as a percentage of TRT  
4 (QED%) for the field and the computer task to investigate the amount of time that each  
5 group exhibited a QE relative to the total aiming time prior to arrow release. These QED%  
6 values were calculated to make sure that aiming time did not account for any QED group  
7 differences.

8  
9 **-Fig 2-**

### 10 11 **2.3.3 Performance**

12 The main performance measure was obtained by measuring the radial error (RE in  $^\circ$   
13 of visual angle) from each arrow's X and Y location to target centre. The corresponding  
14 archery scores were also measured as a 10-0 scale based on the final location (ring color) in  
15 which the (real and simulated) arrows landed (e.g., score of 10 for centre, 1 for outer ring,  
16 and 0 for a miss).

17 **Field task:** An 80 cm blank sheet of paper was placed behind the target sheet to  
18 record arrow penetrations. New blank sheets were placed after each block of 6 arrows for  
19 each participant. In addition, notes of the location of the arrow were taken after each shot,  
20 using binoculars to identify arrow number/location. The X and Y locations of the 24 arrows  
21 for each participant were measured by hand using a graph ruled sheet. The REs from target  
22 centre were calculated and converted to degrees of visual angle by multiplying each value  
23 by  $0.019^\circ$ , which corresponded to 1 cm.

**Computer task:** The joystick's X and Y positions at the time of button release were recorded automatically by the Matlab program and the RE from the target's centre was subsequently calculated. Accuracy measures were converted to degrees of visual angle by multiplying each value by  $0.019^\circ$ , which corresponded to one pixel. In addition, participants' scores (also ranging from 10 to 0) were computed based on what color ring the arrow landed on (8 pixels or  $0.15^\circ$  per ring).

Trials in which participants shot prior to the green light ( $< 6$  s of aiming) were eliminated and these early responses corresponded to  $3.80 \pm 1.13$  % of all experimental trials in experts,  $3.75 \pm 1.17$  % in novices, and  $4.0 \pm 1.25$  % in non-archers.

## **2.4 Statistical Analyses**

For the field task, separate between-participants ANOVAs were used to analyse the overall QED and performance (RE). In addition, t-tests were implemented to compare QE onset/offset timings in the field between expert and novice archers. A second set of between groups repeated measures ANOVAs were used to analyse QE onset/offset, overall QED, and trial accuracy (RE) across the HN and LN conditions in the computer task. The between-participant factor in our analyses was experts and novices for the field task and expert archers, novice archers, and non-archers for the computer task. The QED%, TRT, and performance scores are presented together with field results in Table 1. Pearson correlations were implemented to determine expert-related QED and performance relationships. Significant effects and interactions were evaluated using Bonferroni corrected post-hoc tests. A significance level of  $\alpha = .05$  was established for all statistical analyses. The results and graphs are expressed as means  $\pm$  standard errors of the mean (SE). Effect sizes are reported as partial eta squared values and Cohen's d values when appropriate.

Sample sizes were computed via a priori power calculation based on pilot data and a sample size of 6 participants for each group was required for a  $\beta = .8$ ,  $\alpha = .05$  and an interaction with an effect size of 1.0.

### 3. Results

#### 3.1 Field task

An analysis of QE timings (onset and offset) revealed that experts had earlier QE onsets compared to novices,  $t(20) = 3.66$ ,  $p = .002$ ,  $d = .86$ . The QE offsets were not significantly different ( $p = .057$ ; Fig. 3A). This early onset indicated that experts had overall longer QED,  $F(1,20) = 8.09$ ,  $p = .012$ ,  $\eta_p^2 = .35$ , compared to novice archers ( $1.96 \pm 0.34$  s and  $0.76 \pm 0.1$  s respectively, see Table 1). In addition, it was revealed that experts were more accurate,  $F(1,20) = 18.42$ ,  $p = .001$ ,  $\eta_p^2 = .55$ , compared to novice archers (Fig. 3B).

A Pearson correlation between QED and performance (RE) across all participants revealed a significant linear relationship,  $R^2 = .38$ ,  $p = .006$ , which showed that longer QEDs corresponded to smaller errors (Fig. 3C).

#### 3.2 Computer task

An analysis of QE timings (onset and offset) revealed significant differences in the QE onsets, but not in the offsets. There was a significant group x noise condition interaction for QE onsets,  $F(2, 27) = 9.73$ ,  $p = .001$ ,  $\eta_p^2 = .44$ . The expert archers showed earlier QE onsets in their HN compared their LN condition, and had earlier onsets compared to novices,  $p = .006$ , and non-archers,  $p < .001$ , in the HN condition (Fig. 4A). In addition, non-archers showed the latest onsets of the group in the LN,  $p < .001$  and  $p = .007$ , compared to novices and experts respectively.

In regards to the absolute QED, the early onsets meant that expert archers showed significant increases in their QEDs,  $F(1,27) = 11.96, p < .001, \eta_p^2 = .49$ , between LN ( $2.6 \pm 1.6$  s) and HN ( $3.3 \pm 0.41$  s) conditions,  $p = .001$ . The expert archers' early onsets resulted in longer QEDs compared to novices in the HN condition ( $1.9 \pm 0.21$  s),  $p = .002$ . In addition, non-archers had significantly shorter QED compared to experts,  $p < .001$ , and novices,  $p = .001$ , in the LN ( $1.19 \pm 0.5$  s) condition and shorter from experts in the HN ( $1.2 \pm 0.1$  s) condition,  $p < .001$ , but not different when compared with the novices in this HN condition,  $p > .05$ .

Performance measures (RE) revealed a main effect for noise condition,  $F(1,27) = 34.48, p < .001, \eta_p^2 = .58$ , and group,  $F(1,27) = 6.91, p = .004, \eta_p^2 = .36$ . Participants were more accurate in the LN compared to the HN condition (Fig 4B). In addition, archers were more accurate compared to non-archers,  $p = .009$  and  $p = .015$ , for expert and novice archers versus non-archers respectively. However, there were no RE differences between the expert and novice archer groups,  $p > .999$ .

Significant correlations were observed between QED and RE in both HN,  $R^2 = .41, p < .001$ , and LN,  $R^2 = .45, p < .001$ , conditions across expert, novice, and non-archer groups (Fig. 4C). Thus, longer QEDs corresponded to enhanced accuracy in both noise conditions.

**-Fig 3-**

**-Fig 4-**

### 3.3 Field and computer task

The results (mean  $\pm$  SE) across both field and computer tasks are presented in Table 1. An analysis of QED% on the field task replicated absolute QED results in which experts showed longer QED relative to trial duration,  $F(1,20) = 6.8, p = .02, \eta_p^2 = .31$ . There were

no differences in trial duration between the two archer groups,  $p = .153$ . In addition, experts had higher scores,  $F(1,20) = 12.38$ ,  $p = .003$ ,  $\eta_p^2 = .45$ , compared to novice archers.

The results from the computer task revealed a significant noise condition by group interaction in QED%,  $F(1,27) = 7.11$ ,  $p = .004$ ,  $\eta_p^2 = .37$ . Post hoc tests showed significant group QED% differences in the LN (non-archers versus experts and novice archers, both  $p < .001$ ) and in HN,  $p = .002$ , conditions. Thus, archers (experts and novices) had a longer QEDs relative to the trial duration compared to non-archers (Fig. 2A). Our analysis also revealed that computer task scores were higher,  $F(1,27) = 111.08$ ,  $p < .001$ ,  $\eta_p^2 = .81$ , and TRTs were longer,  $F(1,27) = 7.81$ ,  $p = .01$ ,  $\eta_p^2 = .23$ , in the HN compared to the LN condition. As with RE measures, a group effect,  $F(1,27) = 10.77$ ,  $p < 0.001$ ,  $\eta_p^2 = .46$ , showed that experts and novice archers had better scores compared to non-archers,  $p = .001$  and  $p = .003$ .

3 Table 1. A summary of the results for field and computer tasks

Group		QED (s)			QED%			RE (°)			Score			TRT (s)

4 QED= quiet eye duration; QED%= quiet eye duration as a percentage of trial duration or aiming time; RE= radial error; mean Score  
5 =0-10 range based on ring location; TRT= total response time; LN= low noise and HN= high noise conditions.

#### 4. Discussion

We report a novel attempt to examine quiet eye durations (QED) in archery, both in the field-setting and using a computer-based simulated archery task. We predicted, based on previous research, that the expert archers would show longer QED than novice archers (e.g., see Causer et al., 2010; Williams et al., 2002). Our findings from the archery field task are in accordance with these previous reports indicating longer QEDs in experts compared to novice archers during aiming tasks. In addition, correlation analysis across the archer groups indicated that longer QEDs corresponded to smaller errors. To our knowledge, this is the first report of QEDs in the sport of archery.

In the field task, the archer not only needs to identify the target, but also incorporate multiple variables such as sway, breathing, cross-winds, motor ‘noise’ and sensory feedback into the motor program during the aiming period. We expected that these results would be replicated in our computer task and that the addition of a non-archer group would allow us to make comparisons with different expertise levels (archers vs. non archers and expert vs. novice archers) that could not be implemented in the field, and would better indicate skill-related gaze strategies that result in superior performance. It should be noted that our computer task and the implementation of a visual perturbation of the aiming crosshair results in an artificial situation; it was not our intent to directly mimic archery nor to suggest that computer tasks could replace *in situ* training. Our intention, as per Behan and Wilson (2008) and Klostermann et al (2013), was to examine the gaze strategies during our computer task in an effort to control for the amount of online information that needed to be processed, without the (motor and environmental) variability encountered in the field and

3 between groups. With this novel manipulation we expected to see longer QEDs in the HN  
4 compared with LN condition, which would provide support for the importance of online  
5 control during the QED period. We were also able to show that the QED in experts is  
6 modulated by task requirements. More specifically, experts seemed to be sensitive to the  
7 noise levels and prolonged their QED during higher task complexity (i.e., HN), while non-  
8 experts maintained their performance throughout the conditions. We argue, in line with  
9 previous suggested QE mechanisms mentioned in the introduction (e.g., Causer et al., 2016;  
10 Vine et al., 2017) and in accordance with models of skill-related motor control, that this  
11 extended time for processing incorporates more efficient online control. Furthermore, in our  
12 task, the type and processing of such information is already known, through previous  
13 published reports investigating online control through similar visual perturbations (see  
14 Sarlegna & Mutha, 2015).

15 In the computer task, the noise introduced into the crosshair's path varied from  
16 slower, smoother, and more predictable profiles in the LN condition to faster, jerkier and  
17 more random profiles in the HN condition. Thus, in both conditions, participants were  
18 required to control the joystick during aiming until the arrow was shot; however, in the HN  
19 condition, enhanced monitoring, and greater error corrections were crucial to maintain the  
20 crosshair on the desired location (i.e., "bull's eye") (Weir, Stein, & Miall, 1989).  
21 Performance measures were in accordance with this task complexity effect and participants  
22 were overall less accurate in this HN task compared to the LN task. We also found group  
23 effects in the computer task, with the archers performing better compared to the non-  
24 archers. Radial errors indicated that the non-archers had greater difficulty in positioning the  
25 crosshair on or close to the target centre at the time when they decided to shoot, resulting in

3 lower scores. These timing and accuracy issues may be explained by examining gaze  
4 behaviour during the task.

5 Our analysis of the eye movements showed that archers exhibited longer QEDs  
6 compared to non-archers, in accordance with previous findings showing that QEDs can  
7 discriminate between performance and expertise levels (see Gonzalez et al., 2015).  
8 However, while these field and computer task results do not imply a causal relationship  
9 between QED and performance, they do suggest that some aspects of the aiming strategy  
10 used by the archer groups were used in our computer task. It is also possible that these skill-  
11 related gaze strategies (QE) may have resulted in superior performance. We propose that a  
12 steady gaze fixation or QE aided the archers in keeping track of the joystick's position with  
13 respect to the target and to better predict when the crosshair would be on the target's centre  
14 or positioned as close to the centre as possible. In contrast, the non-archers may have been  
15 distracted by the crosshair's motion and their moment-to-moment joystick adjustments  
16 (online error corrections), resulting in a shorter QE and larger errors. This suggestion is in  
17 accordance with the notion that skilled behaviour incorporates both predictions and (online)  
18 feedback, while non-archers may have relied more on momentary sensory input as they  
19 attempted to correct their errors (Weir et al., 1989; Wolpert & Flanagan, 2001; Wolpert,  
20 Miall, & Kawato, 1998).

21 The QE timings did not reveal significant differences in QED offsets between the  
22 groups or noise conditions. This finding may be due to the addition of noise in the joystick's  
23 path and the need to control the joystick at all times. In addition, offset times did not differ  
24 between groups in the field suggesting that late sensory information was as important in the  
25 field as in the computer experiment to complete the tasks. This result is in accordance with

Klostermann et al.'s (2013) findings, which showed no significant differences in QE offset on their throwing task despite having different levels of final target location uncertainty. Thus, it is noted that in their experiment, information relating to the target came at a late time and despite this, participants adopted an early QE onset, resulting in longer QEDs. Klostermann et al. (2013) also reported facilitatory effects of longer QEDs on performance during high task demand conditions, in which target uncertainty (random target presentation) was incorporated into the motor program (i.e., increased information processing), presumably during the QE.

Körding and Wolpert (2004) provided evidence for the optimal integration of both predictions and sensory feedback for state estimations and suggested that with enhanced uncertainty there is higher reliance on predictions about the target, which are then matched to the actual feedback. Additionally, current research findings suggest that uncertainty about the target is taken into account for online adjustments in which the time available and the cost of making corrections are an important factor, and that this uncertainty increases variability in performance (see Sarlegna & Mutha, 2015). Thus, uncertainty increases variability in performance but enhances the requirement for prediction about the target. In our experiment, it was the experts who revealed earlier QE onsets and longer QEDs in both computer and field tasks and this was more evident in the HN than LN condition in the computer task. An early QE onset may extend the information processing period of a particularly complex task, in accordance with the previously stated programming hypothesis (Williams et al., 2002). However, we further suggest that the experts' earlier QE onsets, which resulted in longer QEDs, were employed to better accommodate the uncertainty of the crosshair's movements to allow for better predictions during the aiming period for the

programming of the motor response. The novice archers also showed longer QEDs compared to controls, indicating that some of this additional processing was taking place.

In our computer task, uncertainty from the noise implemented into the crosshair's path increased the demands for online corrections and modulated QE onsets and QEDs in expert archers. Others have suggested that rapid online corrections caused by changes in target location are somewhat low-level, 'automatic' responses that occur prior to voluntary corrections (Cameron, Cressman, Franks, & Chua, 2009; Day & Lyon, 2000; Diedrichsen, Nambisan, Kennerley, & Ivry, 2004) but that these automatic adjustments may be selectively suppressed with learning (Gritsenko & Kalaska, 2010). Experts may be able to suppress non-functional or time consuming corrections early and implement more efficient volitional and predictive online control. Thus, archers implemented better predictions that resulted in lower error, facilitated by a longer QEDs. In contrast, non-archers may not be able to inhibit these automatic error corrections, which are time consuming and lead to poorer prediction and consequently, poorer, more variable performance. These distracting effects may be reflected by the presence of eye movements outside of the QE.

The fact that the QE is associated with the absence of eye movements ( $> 1^\circ$ ) and is often referred to as a 'fixation' suggests that oculomotor control and likely, attention control are involved in QE, in line with a plethora of published reports highlighting a central role between visuospatial attention and the generation of saccades (Deubel & Schneider, 1996; Jonikaitis & Deubel, 2011; Kowler, Anderson, Doshier, & Blaser, 1995; Rizzolatti et al., 1987). In addition, the inhibition of oculomotor responses plays an important role in maintaining focused attention to be able to make predictions and plan a motor response. Thus, in complex aiming tasks, skill-related effects are a result of the superior ability to

3 override bottom-up attention capture via their top-down goal directed attention control  
4 (dorsal and ventral attention control systems; Corbetta & Shulman, 2002). The early QE  
5 onsets and longer QEDs of the expert group may have been implemented as a result of the  
6 perceived complexity of the task, as previously reported by Williams et al. (2002) and  
7 Klostermann et al. (2013), but may also point to a superior ability to inhibit other responses  
8 intruding into the motor program. In contrast, the late QE onset in non-archers and in  
9 novices during HN compared to experts suggest that they needed extra time to position the  
10 joystick and achieve attentional focus, which may also be the case in the field. Therefore, in  
11 our tasks, the misalignment of attention (to central/critical cues as explained by Ryu et al.,  
12 2016) caused by error corrections and crosshair noise may be costly and result in larger  
13 errors.

14 Vickers (1992, 1996) supported this inhibition hypothesis after observations of a QE  
15 offset during movement initiation, that is, eye movements outside of the QE threshold were  
16 made once the motor response was executed. It follows that the maintenance of attention via  
17 stable gaze (QE) allows for a more efficient integration of online information into the motor  
18 program, which may explain the archers' superior performance. However, these  
19 fixation/inhibition abilities attributed to skilled individuals need to be further investigated.  
20 Previously, researchers investigating anxiety and gaze provide some evidence to suggest  
21 that inhibitory control is taking place during the QE, with performance improving after QE  
22 training under high anxiety conditions (see Vine et al., 2014). Anxiety has been associated  
23 with deficits in attention control and in particular, inhibition (Berggren, Richards, Taylor, &  
24 Derakshan, 2013; Bishop, 2009) due to competing cognitive resources. Additionally, greater

cognitive loads have been shown to increase errors (inhibition) in antisaccade tasks (Berggren et al., 2013).

The beneficial effects of this “quiet” gaze on performance is evident in a number of QE training studies in which training consists of directing gaze to one location and maintaining that gaze for a longer period (Causer et al., 2011; Moore et al., 2012; Vine & Wilson, 2011). This training is believed to maintain focused attention on critical cues and away from distractors. Similarly, a study implementing peripheral blurring of training videos has been shown to improve performance (decision making skills) in novice basketball players (Ryu, Mann, Abernethy, & Poolton, 2016). Ryu et al argued that this manipulation ensured the alignment of gaze and attention to critical central cues, overriding the conscious engagement with peripheral distractors. Further manipulations of target attention/inhibition mechanisms in QE across distinct skill levels may provide insight into the links between QE and attention and how these skills are acquired and used during such aiming tasks.

In line with previous notions that time spent preparing a movement facilitates the development of appropriate actions to minimize errors (Battaglia & Schrater, 2007), and in line with the QE programming hypothesis (Williams et al., 2002), our results suggest that experts use aiming time more efficiently, compared to non-archers. We note, however, that the inhibition and programming hypotheses to explain the benefits of the QED on performance are not exclusive, but that attention/inhibitory mechanisms are needed for effective predictions and thus, accurate programming. Additionally, it is likely that online control and monitoring are important mechanisms that can modulate QED. Further manipulations limiting feedback and/or using other kinds of sensory feedback

(proprioceptive) could provide further insight into this notion. This interpretation suggests interactions between top-down and bottom-up control networks (or dorsal and ventral streams; Corbetta & Shulman, 2002) during target selection and computations for movement parameterization during the QE in goal-directed actions. Therefore, the QE period seems to involve more complex processes than just early programming, as previously thought (Vickers, 2009; Vickers, 2011). We have presented an experimental platform in which further examination of these issues can take place.

## **Conclusions**

Our findings support the growing literature base on the effectiveness and skill-related differences of longer QEDs in aiming tasks. We suggest that the QE is a gaze strategy that allows for the accurate programming and timely selection of a motor response using predictive online control. Suppression of intrusive responses during the preparation-selection period allows for this programming to take place, reflecting the timely inclusion of afferent signals used for prediction. The fact that we were able to see these QED differences in our field-test and in a computer-based archery task now offers the potential to study in more detail the gaze strategies implemented by expert performers and the underlying mechanisms. Understanding how experts strategically control gaze and assign their cognitive resources could be exploited in many other domains outside of sport (e.g., arthroscopic surgery), and could lead to better focused training programs.

**Fig 1.** The image shows the computer experiment with crosshair (representing joystick position), the target (made of 10 multi-coloured circles, equivalent to  $1.5^\circ$  of visual angle, thus,  $0.15^\circ$  per ring) presented on the centre of the screen. The first screen image (1, left) shows the “Go!” signal which alerted the participant of a new trial, which commenced once the participant pressed the joystick’s front button and corresponded to the start of the aiming time. The second screen image (2, left) corresponds to when the participants pressed the joystick’s front button, which made the crosshairs appear at the lower part of the screen ( $4^\circ$  from the target centre). At this time, participants had to pull the joystick to elevate it towards the target (drawback) and continue to aim at the target, while waiting for the green light to appear. The third image shows when the green light appeared after the 6 s of this continued aiming and flashed for a total duration of 0.25 s. The fourth image shows the time given to participants to shoot (button-release) at the target after the green light had disappeared (6.25 s) and within the 30s limit (from button press). The fifth and final image (5, right) shows where the arrow landed on the target after button-release and shown as feedback (2 s). The sizes of 10 ring target (2 rings per color), background, green cue, and crosshair shown are for schematic purposes and are not to scale.

**Fig 2.** An example of a participant’s eye movements corresponding to vertical (EOGv) and horizontal (EOGh) traces (converted to  $^\circ$  of visual angle from EOGh and EOGv voltage calibration regressions) during the Total Response Time (TRT). The QE boundaries are set at a  $1^\circ$  threshold (0.5 and -0.5 from target centre). Eye movements fall outside of the  $1^\circ$  boundary, thus establishing a QE onset/offset. The QE onset was identified after the green light which appeared after 6 s of aiming and for a duration of 0.25 s. Blinks were eliminated and typically spotted outside the QE.

**Fig 3.** Field task Quiet Eye onset and offset (A) across aiming time, Radial Error (B) between experts and novices and Quiet Eye Duration (QED) and performance (Radial Error) correlations across all archer groups (C). Graph A depicts QE onset/offset timings which were examined by moving backwards from arrow release. QE timing analysis (A) showed earlier onsets and thus, longer QEDs in experts compared to novices,  $p < .5$ . Experts were more accurate and in addition, a significant correlation (C) showed that longer QEDs corresponded to better performance,  $p < .5$ .

**Fig 4.** Computer task QE onset and offset (A), Radial Errors (B) between experts, novices and non-archers across High Noise (HN) and Low Noise (LN) conditions; and correlations between QED and performance (C) across all groups. Experts again showed earlier QE onsets and longer QEDs in the HN; while non-archers showed the latest onsets and shorter QEDs in the LN (A),  $p < .5$ . Radial errors showed that all groups performed better in the LN compared to the HN and that archer groups exhibited lower errors compared to non-archers,  $p < .5$  (B). As in the field task, significant correlations were observed in the LN and the HN tasks,  $p < .5$ , (C).
